Abstract

Biometric system performance can be improved by means of data fusion. Several kinds of information can be fused in order to obtain a more accurate classification (identification or verification) of an input sample. In this paper we present a method for computing the weights in a weighted sum fusion for score combinations, by means of a likelihood model. The maximum likelihood estimation is set as a linear programming problem. The scores are derived from a GMM classifier working on different feature extraction techniques. Our experimental results assessed the robustness of the system in front changes on time (different sessions) and robustness in front of changes of microphone. The improvements obtained were significantly better (error bars of two standard deviations) than a uniform weighted sum or a uniform weighted product or the best single classifier. The proposed method scales computationally with the number of scores to be fused as the simplex method for linear programming.

1. Introduction

Biometric recognition (Faundez-Zanuy, 2006) offers a promising approach for security applications, with some advantages over the classical methods, which depend on something you have (key, card, etc.), or something you know (password, PIN, etc.). A nice property of biometric traits is that they are based on something you are or something you do, so you do not need to remember anything neither to hold any token.

On the other hand, they have an important drawback, because if a person’s biometric data is stolen, it is not possible to replace it (Faundez-Zanuy, 2004). Probably, these drawbacks have slowed down the spread of use of biometric recognition (Faundez-Zanuy, 2005b). For those applications with a human supervisor (such as border entrance control), this can be a minor problem, because the operator can check if the presented biometric trait is original or fake. However, for remote applications such as internet, some kind of liveliness detection and anti-replay attack mechanisms should be provided. Fortunately, speech offers a richer and wider range of possibilities when compared with other biometric traits, such as fingerprint, iris, hand geometry, face, etc. For instance, you can use a text-dependent system (Faundez-Zanuy and Monte-Moreno, 2005) and to ask the user for a specific speech sentence. Speaker recognition does not offer the same robustness and precision than other biometric traits such as fingerprint and iris. However, strong efforts are done to enhance the performance, due to its particular set of characteristics that can permit to manage some vulnerability attacks.
This paper is organized as follows: Section 2 describes the different data levels for fusion with special emphasis on the score level. A new strategy is presented for data fusion. Section 3 is devoted to the experimental results, and Section 4 summarizes the main conclusions.

2. Data fusion

2.1. Introduction

Given a biometric system, such as that depicted in Fig. 1, four main data fusion levels can be defined: sensor, feature, score (also known as opinion) and decision. The description of these levels is beyond the scope of this paper and can be found in (Faundez-Zanuy, 2005a).

In this paper we will focus on the score level. This kind of fusion is also known as confidence level. Given a set of classifiers (matchers), it consists of the combination of the scores provided by each matcher. The matcher just provides a distance measure or a similarity measure between the input features and the models stored on the database.

It is possible to combine several classifiers working with the same biometric characteristic (unimodal systems) or to combine different ones. In our case, it will be a unimodal combination, where both classifiers share the same input signal, as depicted in Fig. 2. This scheme can be easily generalized for more than two matchers.

2.2. Combination strategies

The score combination schemes for a given speaker can be done in several ways (see Kuncheva, 2004). The most natural strategies for combining different scores, might be

1. Weighted sum: \( O_s = \sum_{j=1}^{N} h_j o_j \).
2. Weighted product: \( O_s = \prod_{j=1}^{N} (o_j)^{h_j} \).

In this paper we propose a fusion method, where the scores will be interpreted as probabilities of an observation, given a model. For each observation we will have a vector of \( N \)-scores, which will be the probability of the identity of a speaker obtained from a set of \( N \) classifiers. The global likelihood function will be the product of the all the probabilities (scores) of all speakers where each score (\( O_s \)) will be weighted by a factor \( h_j \) that will be specific for that score. The likelihood function of these probabilities can be understood as a fusion of either a weighted product of probabilities, or a weighted sum of logarithms of probabilities.

The estimation of the \( h_j \) parameters that weight the different scores can be done by several methods. The first and most simple might be the brute force method, which would consist on exploring the space of possible recognition rates for all possible combinations of a set of discrete values of the weighting parameters. The problem with this method
is that it scales exponentially with the number of scores, and therefore it only has sense for a small value of the number of scores to be merged (i.e. \( N = 2, 3 \)). Another possibility might be the use of a least squares method for the estimation of the weighting parameters, without considering a likelihood model. The use of a least squares method will assign to the members of a given class the target value \( Q^\text{target} = +1 \), and to the other examples the target \( Q^\text{target} = -1 \). The advantage of a least squares estimation is that it might take into account the possible correlations (positive or negative) between scores. This method was taken into consideration at the beginning of the project, but had several drawbacks: (a) the introduction of restrictions on the set of parameters \( h_j \) (i.e. \( h_j \geq 0 \)) was artificial, and produced as a result a set of equations had to be solved as a nonlinear convex optimization problem (Boyd and Vandenberghe, 2004), (b) the natural way of setting the least squares problem was as a discriminative estimation (i.e positive vs. negative examples), which gave rise an inconsistent system of equations.\(^1\) The use of a discriminative model was discarded because the set of equations to be solved by the least squares method \( A^h b \) and \( h \geq 0 \) (where \( A \) is a matrix data, and \( b \) is the target vector, with values \( \pm 1 \)) was inconsistent, probably due to the fact that the classes were highly unbalanced and a fraction negative examples were similar to examples of the class assigned +1.

The problem of identifying the subset of the training data examples were similar to examples of the class assigned +1. The consistency was tested by means of the simplex algorithm (for instance see Bertsimas and Tsitsiklis, 1997). The inconsistency was artificial, or can give rounding errors for \( h_j \gg 1 \). Another reason for selecting a solution in a simplex is that the optimization algorithm will allocate a limited ‘budget’ of probability between the different scores, and therefore the scores that contribute marginally to the correct fusion will be given low values of \( h_j \) (notice that \( h_j = 0 \) makes the parameterization irrelevant), while the rest of the probability budget will be allocated to the parameterizations that most contribute to the correct fusion.

The function to be maximized (1) can be set for a given speaker \( s \) as a log-likelihood function

\[
h = \arg \max \left\{ \sum_{j=1}^{M} \sum_{i=1}^{N} h_j \ln(P_{s,j}(x_i)) \right\},
\]

subject to

\[
\begin{align*}
\sum_{j=1}^{N} h_j & = 1, \\
h_j & \geq 0,
\end{align*}
\]

Our objective is to find the vector \( h \) that maximizes simultaneously the likelihood for each speaker. We decided to express the optimization problem with a restriction on each speaker in order to control a common margin, so that each speaker will have a likelihood at least as high as the value of a positive threshold. Notice that if the objective function in (2) had a sum for all speakers, we would not be able to control the likelihood of the worst speaker. Therefore we introduced a new variable which is the common positive threshold for the likelihoods of all speakers, denoted as \( \delta \), and the result of the optimization process will be the value of \( \delta \) plus the values of \( h \) that are compatible with the restrictions.

This problem can be expressed in a convex optimization framework (Boyd and Vandenberghe, 2004) as

\[
\delta \rightarrow \max \quad \Delta \text{Weight \( \delta \)},
\]

subject to

\[
\begin{align*}
A^h & \geq \delta e, \\
\sum_{j=1}^{N} h_j & = 1, \\
h_j & \geq 0, \\
\delta & \geq 0,
\end{align*}
\]

where \( A \) is a matrix of \( S \times (M \times N) \) with the following structure:

\[
A = [A^1 \ldots A^k \ldots A^s]^T
\]
and each $A^k$, with $k = \{1, \ldots, S\}$ is a submatrix of $(M \times N)$ composed by $d^k_{ij} = \ln(P_{i,j}(x))$. The optimization variable is $\delta$ and $e$ is a column vector of dimension $(M \times S)$. The restrictions on the function to be maximized (2) is that, simultaneously for all speakers, the weighted scores of every utterance of speaker $s$, $\sum_{j=1}^{S} h_j \ln(P_{s,j}(x))$ will have a higher value than the variable to be maximized $\delta$. This variable is weighted in the objective function by a parameter that we will denote as $\Delta$ weight, which can be seen as a scale factor over the log probabilities, which will work as a trade-off in the simplex $\sum_{j=1}^{S} h_j = 1$ generated by $h^*_j$. Low values of the $\Delta$ weight will give solutions near a vertex of the simplex, while high values will give solutions near a vertex of the simplex.

This value might be seen as a prior over the $\Delta$ weight, which can be controlled by means of this parameter.

This optimization problem is solved by means of the simplex algorithm$^2$ (Bertsimas and Tsitsiklis, 1997). The problem (3) can be expressed as a standard linear programming problem

$$\min_{x} \quad f^T x,$$

subject to

$$Ax \leq b,$$

$$A_{eq} x = b_{eq},$$

$$lb \leq x \leq ub,$$

where $A$ is the matrix of log probabilities, defined in (3) and $f$, $x$, $b$, $b_{eq}$, $lb$, $ub$ and $A_{eq}$ are vectors defined as

$$f = \left[0, \ldots, 0, \Delta \text{Weight} \right]_{N}^T,$$

$$x = [h_1, h_2, \ldots, h_N, -\delta]^T,$$

$$b = [0, \ldots, 0]^T,$$

$$b_{eq} = [1]^T,$$

$$lb = [0, \ldots, 0]^T,$$

$$ub = [1, \ldots, 1]^T,$$

$$A_{eq} = \left[ \begin{array}{c} 1 \\ \vdots \\ 1 \\ 0 \end{array} \right]_{N}^T.$$

The method we propose has several computational advantages, perhaps the most interesting is that the average case running time for the simplex algorithm polynomial bounded. Although some examples can be constructed where the simplex algorithm can take an exponential time with the number of constraints, the mean time, is a polynomial of the number of constraints, which makes the solution quite inexpensive from the computational point of view (Bertsimas and Tsitsiklis, 1997). This fact is important, because each observation will be a constraint.

3. Experimental results

3.1. Database

The Gaudi database (Ortega-García et al., 2000; Satue and Faundez-Zanuy, 1999) was originally designed in order to measure the performances under different controlled conditions: language, interval session, microphone. The corpus is composed by

- Forty-nine speakers.
- Four sessions with different tasks: isolated numbers, connected numbers, read text, conversational speech, etc.
- For each session, the utterances were acquired in two languages (Catalan and Spanish) and simultaneously with different microphones as described in Table 1.

In this contribution, the training protocol consists of using one reading text of an average duration of one minute (using session 1 and MIC1). Concerning the tests, we use five phonologically balanced utterances (Spanish) identical for all the speakers through the scenarios M3 to M6 (cf. Table 2). We focus on the third first sessions with different microphones The number of tests for genuine users is $49 \times 5 = 245$ for each session and the average score is estimated under $49 \times 5 \times 6 = 1470$ tests.

The speech signal has been down-sampled to 8 kHz, pre-emphasized by a first order filter whose transfer function is $H(z) = 1 - 0.95z^{-1}$ and normalized between $-1$ and $+1$ (for cumulant estimation). A 30 ms Hamming window is used, and the overlapping between adjacent frames is 2/3. A

3.2. Feature extraction

State-of-the-art feature extraction methods are based on the MFCC (mel frequency cepstral coding) or the LPCC (linear predictive cepstral coding). These short-term features are currently used in GMM based speaker recognition systems. Alternative features have been investigated resulting on different approaches. The first ones consist of the development of short-term features (as LPCC or MFCC) such as the use of signal decomposition methods (wavelet, independent component analysis). Other techniques aim to exploit other levels of representation such as phonetic, prosodic, idiolectal, dialogic or semantic (Faundez-Zanuy and Monte-Moreno, 2005). These features are extracted from long-term physical traits and are usually fused with the traditional spectral features (short-terms).

In this contribution, we propose to evaluate additional short-term features that can also be combined with the MFCC/LPCC ones. These features are extracted from the LP-residue.

3.2.1. Feature extraction from the residue

Speech signals are assumed to result from the excitation of the vocal tract according to the source-filter model. Following the LPC analysis framework, the vocal tract is associated to the filter (LPC coefficients) and the excitation to the residual signal. The LP analysis consists of the estimation of LPC coefficients by minimizing the prediction error. The predicted sample results from a linear combination of the $p$ past samples (Atal and Hanauer, 1971)

$$\hat{s}(n) = \sum_{k=1}^{p} a_k s(n-k).$$

(6)

The LPC coefficients $a_k$ are related to the vocal tract and should also partly capture speaker-dependent information. Indeed, derived features from these coefficients, namely the linear predictive cepstral coding (LPCC), are intensely used in speaker recognition tasks. The parameter $p$ (filter’s order) plays a major role. For instance in speech recognition tasks the best scores are obtained with 12th order whereas in speaker recognition the most used order is 16.

Within the traditional LP analysis, the residual is obtained by the error between the current and the predicted samples

$$r(n) = s(n) - \hat{s}(n).$$

(7)

Theoretically, the residual is uncorrelated with the speech signal and it is related to the excitation which is speaker-dependent. These features are known as source features. However, recent works on nonlinear speech processing have shown that the source-filter model is not suitable for the speech production modelling (Faundez-Zanuy et al., 2002; Kubin, 1995). Different phenomena occur during the production, that are nonlinear and chaotic. From these investigations on nonlinear processing, one can assume that there is a dependency between the speech signal and the residual.

Several investigations have been carried out for the use of this residual for the improvement of speaker recognition systems (Thevenaz and Hügli, 1995; Faundez-Zanuy and Rodriguez, 1998; Mary et al., 2004; Yegnanaraya et al., 2001; Mahadeva Prasanna et al., 2006; Zheng et al., 2006). Thevenaz and Hügli (1995) exploit the theoretical orthogonality between two models respectively the filter (i.e. the LPC coefficients) and the residue. Their results confirm the complimentary of these representations for speaker verification. Neural networks have been also tested for the characterisation of the LP residual (Mary et al., 2004). In (Mahadeva Prasanna et al., 2006), auto-associative neural networks are used for the characterisation of the linear residue. They show that speaker recognition systems can reach efficient rates by using only residual features.

In this contribution, we propose to exploit the fact that the residue conveys all information that are not modelled by the LPC filter (cf. Eq. (7)). These informations are modelled by two techniques: temporal and frequential. The first approach attempts to model the residual signal by an auto-regressive (AR) model while the second one is based on a filter bank based model.

3.2.2. Temporal approach

The temporal approach is based on an auto-regressive (AR) model of the LP-residue

$$\hat{r}(n) = - \sum_{k=1}^{\rho} a_k r(n-k),$$

(8)

where $r$ and $\rho$ respectively represent the LP-residue and the filter’s order.

Auto-regressive coefficients (i.e. LPC features) are not directly used in speech applications. LPCC features obtained from the LPC by a cepstral transformation are preferred due to their decorrelation properties suitable for diagonal matrices based models (GMMs). The $a_k$ coefficients are transformed on cepstral ones $c_k$ similarly to the LPC–LPCC transformation. The obtained cepstral features are known as the R-SOS-LPCC since they are obtained from a cepstral transformation of an AR modelling of the LPC residue.

3.2.3. Frequential approach

Contrary to the previous approach, in this section, we describe a frequential processing of the residual signal $r(n)$. This approach was originally proposed by Hayakawa et al. (1997) and called by them the power difference of spectra in sub-band (PDSS). They tested it on a speaker identification problem, the R-PDSS features gave a rate
of 66.9% and the combination with LPCC features gave 99% (99.8% for the LPCC alone).

The R-PDSS features are obtained by the following steps:

- Calculate the LP-residual $r$.
- Fast Fourier transform of the residual using zero padding in order to increase the frequency resolution: $S = |\text{fft}(\text{residue})|^2$.
- Group the power spectrum into $M$ sub-bands.
- Calculate the ratio of the geometric to the arithmetic mean of the power spectrum of the $i$th sub-band and subtract it to 1

$$R - \text{PDSS}(i) = 1 - \frac{\left(\prod_{k=i}^{H_i} S(k)\right)^{\frac{1}{N_i}}}{\frac{1}{N_i} \sum_{k=i}^{H_i} S(k)},$$

(9)

where $N_i = H_i - L_i + 1$ is the number of sample number of frequency points in the $i$th sub-band. $L_i$ and $H_i$ are respectively the lower and upper frequency limits of the $i$th sub-band. The same bandwidth is used for all the sub-bands.

Cepstrum analysis of the residual has been also investigated in speech recognition (He et al., 1996): filter bank analysis of the one-sided auto-correlation of the residual $r$ plus a cepstral transformation. The obtained features named as RCEP (residual cepstrum) present some linguistic information and in combination to the LPCC improves the recognition rates.

### 3.3. Feature linearization

Communications channel can be modelled as a linear filter, in a simplest case, or as a Wiener system: linear filter $h(t)$ followed by a nonlinear invertible function $f(.)$ (see Fig. 3). Many researches have been done in the identification and/or the inversion of linear and nonlinear systems. These works assume that both the input and the output of the distortion are available (Prakriya and Hatzinakos, 1985); they are based on higher-order input/output cross-correlation (Bellings and Fakhouri, 1978) bispectrum estimation (Nikias and Petropulu, 1993; Nikias and Raghuveer, 1987) or on the application of the Bussgang and Prices theorems (Boer, 1976; Jacoviti et al., 1987) for nonlinear systems with Gaussian inputs.

However, in real world situations one often does not have access to the input. In this case, blind identification becomes the only way to solve the problem.

One of the main sources of degradation in speaker recognition is the mismatch between training and testing conditions. This is due because in most of the situations we can not control the channel effects over the speech signal. It means that the parameters extracted in the recognition stage can be modified for the channel effects and can cause that system fails to recognize an authorized speaker.

In order to minimize the channel effects, we try to homogenize the channel effects by means of a linearization procedure. Other strategies can be found in (Solé-Casals and Faudez-Zanuy, 2006).

We use a homogenization method inspired on recent advances in source separation of nonlinear mixtures (see Solé-Casals et al., 2002; Taleb and Jutten, 1999; Taleb et al., 2001; for details). Based on the inversion of Wiener systems or post-nonlinear mixtures in BSS/ICA context, we propose to Gaussianize the speech signal before to extract the parameters as is done in (Solé-Casals et al., 2005).

#### 3.3.1. Cumulative density function

The simplest approach for roughly computing $g(.)$, the inverse of $f(.)$, is based on the property of the cumulative density function (cdf). Consider the random variable $E$, and denote its cdf $F_E = \text{Pr}(E < u)$, where $\text{Pr}()$ denotes the probability. The random variable $U = F_E(E)$ is then uniformly distributed in $[0,1]$. Denoting by $\Phi(u)$ the Gaussian cdf, which transforms a unit variance Gaussian variable into a uniform random variable in $[0,1]$, it is clear that $\Phi^{-1}(u)$ is a unit variance Gaussian random variable. Then, a simple Gaussianization procedure (see Fig. 4) is to apply this direct method, provided we have the function $\Phi^{-1}(.)$, by using the following nonlinear mapping:

$$g = \Phi^{-1} \circ F_E.$$

(10)

#### 3.3.2. Maximization of Shannon entropy

Let $p_z(u)$ denote the probability density function of $Z$, the Shannon entropy of the unit variance random variable $Z$, defined by

$$H(Z) = \int - \log(p_z(u)) p_z(u) du$$

(11)

Fig. 3. The unknown Wiener system (top) and the proposed inversion structure, a Hammerstein sistem (bottom). Nonlinear function $g(.)$ should be the inverse on unknown function $f(.)$ and linear filter $w$ should be the inverse of unknown filter $h$.

Fig. 4. The system Gaussianization for a speech signal $e(t)$. The first block consists in estimating the cumulative density function (cdf) of the observed signal and the second block is the inverse of the Gaussian cdf.
is maximum if $Z$ is Gaussian (Cover and Thomas, 1991). Then, another Gaussianization method can be obtained so that $H(Z)$ is maximum (under the constraint of unit variance).

### 3.3.3. Algorithms

Using the previous results, one can propose two algorithms for the linearization (Gaussianization) of the speech signal. The first algorithm is based on formula (10). The Matlab code is very simple and very fast. A second algorithm, based on (11), consists of adjusting a nonlinear mapping $g$ so that the Shannon’s entropy of $Z = g(E)$ is maximum under the constraint $Ez^2 = 1$. Although the second idea is still quite simple, it leads to an algorithm which is much more complicated and requires much iterations before converging to an acceptable solution. On the contrary, the algorithm based on (10) provides an analytical solution without any iterations. In the following, we only consider this fast algorithm.

### 3.4. Classification

The classification system is based on the standard Gaussian mixture models (GMMs) (Reynolds and Rose, 1995). A Gaussian mixture density is a weighted sum of $K$ component densities given by

$$P(x|\lambda) = \sum_{k=1}^{K} o_k g_{(\mu_k, \Sigma_k)}(x),$$  \hspace{1cm} \text{(12)}

where $x$ is a $d$-dimensional vector, $g_{(\mu_k, \Sigma_k)}(x)$ are the component densities and $o_k$ the mixture weights. Each component density is a $d$-variate Gaussian function

$$g_{(\mu_k, \Sigma_k)}(x) = \frac{1}{(2\pi)^{d/2} \sqrt{\det(\Sigma)}} e^{-1/2(x-\mu)^T\Sigma^{-1}(x-\mu)}.$$ \hspace{1cm} \text{(13)}

With mean vector $\mu_k$ and covariance matrix $\Sigma_k$. The mixture weights $o_k$ satisfy the following constraint:

$$\sum_{k=1}^{K} o_k = 1.$$ \hspace{1cm} \text{(14)}

The Gaussian mixture model is defined by the mean vectors, covariance matrices and mixture weights. The set of parameters is grouped and represented by

$$\lambda = (w_k, \mu_k, \Sigma_k) \quad k = 1, \ldots, K.$$

Each speaker is modelled by a GMM with 32 mixtures and diagonal covariance matrices.

### 3.5. Normalization of the scores

In the case of fusion it is usual to introduce a normalization of the scores, so that the fusion is done on adimensional units, which behave in a statistically similar fashion. In our case, there was no need of normalizing the distance measures. The set of classifiers to be merged were homogeneous, and the only difference was due to the parameterization.

### 3.6. Results of the linear programming fusion

We have compared the fusion method based on linear programming with a uniform weighting of each parameterization (i.e. the mean value) and with the best single parameterization (i.e. MFCC).

Another possibility was to compare the results of the fusion with the parameterization (or a subset of parameterizations) that gave the best results. The results did not show a consistent behaviour. Some parameterizations were better in the sense of robustness in front of a change of session, but had a bad performance when the microphone was changed, and others degraded with a change of microphone. In any case the fusion method based on the linear programming method consistently improved over the best method alone. For comparisons purposes we will present the results of the two different fusion methods with the recognition results of the parameterization that globally gave the best results, i.e. MFCC.

The experiments were designed in order to see the robustness of the fusion method with respect to either a change of session or a change of microphone. As reference we took the best possible scenario: M1 (see Section 3.1), which consisted of training with session 1 and microphone

Fig. 5. Box plot of the distances of all the utterances, ordered by parametrization.

The margin of variation of the measures was similar, as can be seen in Fig. 5.

The parametrization titles are shown in Table 3.
1 and with four of the five phrases and recognizing with the left out phrase. This was repeated for all the phrases, and the results are shown in Fig. 6.

In all figures, the error bars represent two standard deviations, i.e. a confidence interval of 95%. Notice that the use of the linear programming model always improves significantly the recognition rate for the different test sentences in the reference set up.

The Delta weight, as explained in Section 2.2 controls the flatness of the weighting vector. The experiments showed that low values of the delta weight gave a near uniform distribution of the weights, while high values, selected the weights that can be understood as the most relevant. Notice that as the training was not discriminative, the parameterization with the highest values \( h_j \) should not be taken as the most discriminative, but as the ones that contribute more to the likelihood of the data given the model. Fig. 7 shows the values of the \( h_j \) for values of the Delta weight = \{1, 10\}.

The first experiment of interest is the robustness of the method with respect to a change in the date of the recording (i.e. the session), but without changing the microphones, which correspond to scenarios M3 and M5. We computed the weighting parameters \( h_j \) on scenario M1, and tested with M3 and M5. In case of M3, which corresponds to session 2, the sentences 4 and 5 were not distinguished, and in session M5, the use of a high value of Delta weight, yields a significative improvement. See Figs. 8 and 9. Also both methods (linear programming and uniform weighting) give better results than the best parametrization alone.

The second experiment would be the robustness in front to a change of microphone; which is scenario M2, and a simultaneous change of microphone and session scenarios M4, and M6. We computed the weighting parameters \( h_j \) on scenario M1, and tested on scenarios M2, M4 and M6. It can be seen in Fig. 10 that in the case of M2 where the recognition rates are already high, a near
Fig. 8. Robustness of the method with respect to a change in the date of the recording. Setting M3 for Delta weights: 1 (left), 10 (right). Lower dots, correspond to the results of the MFCC alone.

Fig. 9. Robustness of the method with respect to a change in the date of the recording. M5 for Delta weights: 1 (left), 10 (right). Lower dots, correspond to the results of the MFCC alone.

Fig. 10. Robustness of the method with respect to a change in the microphone. Scenario M2 for Delta weights: 1 (left), 10 (right). Lower dots, correspond to the results of the MFCC alone.
uniform weighting is better in the sense that the use of a delta weight equal to one gave a consistent improvement over all the phrases, while a high value of the delta weight, which is associated to a highly non uniform weighting, lowered the recognition rate. On the other hand as can be seen in Figs. 11 and 12, with a the simultaneous change of session and microphone, the method proposed in the paper, yields a consistent improvement over a uniform weighting of each score and the globally best parametrization.

4. Conclusions

We have presented a fusion method for likelihood model of the different channels to be fused. The method is based on a linear weighting of the log likelihood of the data given a model, and the weighting parameters are estimated on a geometrical simplex. The algorithm for the maximum likelihood estimation of the weighting parameters was set as a linear programming problem, with a free parameters. The free parameter determines the uniformity of the weighting vector. The experiments showed that the presented fusion method gives robustness in front of a change of microphone and a change of session, i.e. the improvements were statistically significative with respect to a uniform weighting or to the best single parametrization.
